Descriptions of studies and measurements

Cohort on Diabetes and Atherosclerosis Maastricht (CODAM)

Cohort description

The CODAM (Cohort on Diabetes and Atherosclerosis Maastricht) study is a cohort study including 574 subjects with an elevated risk of type 2 diabetes mellitus and cardiovascular disease.(1) This study was initiated in 1999. In short, participants were selected from a large population-based cohort.(2) Inclusion criteria were a Caucasian descent and age > 40 years and, in addition, at least one of the following: body mass index (BMI) >25 kg/m²; a positive family history of type 2 diabetes mellitus; a history of gestational diabetes and / or glucosuria; and use of anti-hypertensive medication. Study participants were extensively characterized with regard to their metabolic, cardiovascular and lifestyle profiles during two visits to the University's research unit. The CODAM study was approved by the Medical Ethical Committee of the Maastricht University Medical Center, and all participants gave written informed consent.

Depression

During the first visit through the research unit, participants underwent an Oral Glucose Tolerance Test (OGTT) during which they completed several questionnaires, including a questionnaire on depression. Depressive symptoms were measured with the Center for Epidemiologic Studies Depression Scale (CES-D),(3) a 20-item self-report scale designed to measure depressive symptomatology in the general population (score range 0-60, with higher scores indicating higher severity of depression. A score of ≥16 is used to identify individuals at risk for clinical depression, with good sensitivity and specificity and high internal consistency.(4) This cut-off was used to distinguish persons with and without depression for the present study.

Blood sampling

Blood samples were taken during the same day as the depression questionnaire. Subjects were asked to stop their lipid-lowering medication 14 days before the first visit and all other medication was stopped the day before the visit (>80% adherence). Blood samples were obtained by venipuncture. EDTA plasma aliquots were stored at -80°C until use. In the current study, two subcohorts were defined: CODAMDM (type 2 diabetes) and CODAMnoDM (no type 2 diabetes, with central obesity), because the metabolites of these subgroups were measured at two separate occasions (November 2014 and May 2015, respectively) at Brainshake Ltd./Nightingale Health. In CODAM, a total of 112 participants had a depression (CODAMDM N=34, CODAMnoDM N=78, whereas 443 participants had no depression (CODAMDM N=105, CODAMnoDM N=338).

The Maastricht Study (TMS)

Cohort description

The Maastricht Study (5) is a prospective observational population-based cohort study focusing on the etiology, pathophysiology, complications and comorbidities of type 2 diabetes mellitus. In this study individuals with type 2 diabetes mellitus were oversampled. In brief, eligible participants were selected based on age (between 40 and 75 years) and place of residence (the Southern part of the Netherlands). Recruitment proceeded through mass media campaigns, municipal registries and the regional Diabetes Patient Registry via mailings.

Depression

Depressive disorder was assessed by the Mini-International Neuropsychiatric Interview (MINI).(6) The MINI is a short diagnostic structured interview, used to assess the presence of current major depressive disorder (MDD) in lifetime and in the preceding 2 weeks according to the DSM-IV (Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition). For the present study, persons with depression were defined as having a MDD in lifetime. Controls were defined as persons without a depressive disorder according to the MINI.

Blood sampling

After overnight fasting, EDTA plasma was collected in EDTA tubes on ice, separated after centrifugation, and stored at -80°C until the assays were performed. The time between collection and storage was less than 2 hours. Samples were collected from April 2010 until April 2013. In the current study, two subcohorts were defined: TMSDM (type 2 diabetes) and TMSnoDM (no type 2 diabetes, with central obesity), because the metabolites of these subgroups were measured at two separate occasions (November 2014 and May 2015, respectively) at Brainshake Ltd./Nightingale Health. The study was approved by the institutional medical ethical committee. All participants gave written informed consent. EDTA plasma samples were available for 515 persons with depression (TMSDM N=272, TMSMnoDM N=243) and 1002 non-depressed controls (TMSDM N=503, TMSnoDM N=480).

Erasmus Rucphen Family (ERF) study

Cohort description

The Erasmus Rucphen Family (ERF) study is a large family-based cohort study aiming to identify genetic risk factors in the development of complex disorders, in a young genetically isolated population in the Southwest of The Netherlands.(7) Possible participants were selected based on genealogical background. Eligible participants included three generations of living descendants, of twenty couples with at least six children living in the community in the 19th century. Genealogical information on this population was reconstructed using church and municipality records. All living descendants of these families aged 18 years and older, as well as their spouses, were invited to attend a series of clinical examinations. Data were collected between June 2002 and February 2005. The medical ethical committee of the Erasmus Medical Center, Rotterdam approved the study and informed consent was obtained from all participants.

Depression

Symptoms of depression were assessed using the HADS(8) and the CES-D(3) in 2385 participants. The CES-D is a 20-item self-report scale designed to measure depressive symptomatology in the general population (score range 0-60, with higher scores indicating higher severity of depression. A score of ≥ 16 is used to identify individuals at risk for clinical depression, with good sensitivity and specificity and high internal consistency.(4) The HADS consists of a 14-item self-report questionnaire incorporating seven questions for anxiety and seven others for depression. ⁸ Each item is scored 0 to 3, and a total score of 8 or greater on the HADS-depression (HADS-D) and HADS-anxiety (HADS-A) subscale indicates the presence of an depressive or anxiety disorder, respectively. For the current study, cases with depression were defined as having a CES-D ≥ 16 and/or HADS-D ≥ 8 . Controls were defined as having a CES-D < 16 and HADS-D < 8 and never reporting any depressive or psychiatric disorder during one of the measurements.

Blood sampling

EDTA plasma samples were collected after overnight fasting. Samples were drawn by venipuncture from the median cubital vein. After centrifugation, plasma was aliquoted and stored at -80°C. Samples were not thawed prior to shipment to Brainshake Ltd./Nightingale Health for analysis. Samples were measured in April 2014 at Brainshake Ltd./Nightingale Health. This was done for 153 participants with depression and 193 controls.

Leiden University Migraine Neuro-Analysis (LUMINA)

Cohort description

Participants of the Leiden University Migraine Neuro-Analysis (LUMINA)(9) were recruited through a nationwide website inviting migraine patients and non-migraine controls to participate in migraine research. In addition, patients attending the Leiden University Medical Centre (LUMC) dedicated headache clinic were invited to participate. Hence, persons with migraine are oversampled.

Depression

Symptoms of depression were assessed using the HADS(8) and the CES-D.(3) The CES-D is a 20-item self-report scale designed to measure depressive symptomatology in the general population. A score of ≥ 16 is used to identify individuals at risk for clinical depression, with good sensitivity and specificity and high internal consistency.(4) The HADS consists of a 14-item self-report questionnaire incorporating seven questions for anxiety and seven others for depression. Each item is scored 0 to 3, and a total score of 8 or greater on the HADS-depression (HADS-D) and HADS-anxiety (HADS-A) subscale indicates the presence of an depressive or anxiety disorder, respectively. For the current study, cases with depression were defined as having a CES-D ≥ 16 and/or HADS-D ≥ 8 . Controls were defined as having a CES-D < 16 and HADS-D < 8 .

Blood sampling

After an overnight fast, EDTA plasma samples were collected. Blood samples were drawn by venipuncture from the median cubital vein, after centrifugation on room temperature; plasma was aliquoted and stored at -80°C . Samples from 59 persons with depression and in 172 controls were sent to Brainshake Ltd./Nightingale Health for analysis; samples were measured in April 2014.

Netherlands Epidemiology of Obesity Study (NEO)

Cohort description

The NEO Study was designed for extensive phenotyping to investigate pathways that lead to obesity-related diseases. The NEO study is a population-based, prospective cohort study that includes 6,671 individuals aged 45–65 years, with an oversampling of individuals with overweight or obesity. Participants were recruited via general practitioners, advertisements and through municipalities in the West of the Netherlands. Data collection took place between September 2008 and September 2012. During the study visit, participants underwent an extensive physical examination and blood sampling. Prior to the visit, various questionnaires were completed. Participants are currently being followed for the incidence of obesity-related diseases and mortality.

Depression

Prior to the study visit, the 30-item self-report inventory of depressive symptomatology (IDS-SR) was used to measure depression symptoms.⁽¹⁰⁾ Scores between 0 and 84 can be obtained and higher scores reflect more depressive symptoms. This IDS-SR has good psychometric properties.⁽¹¹⁾ The established cut-off of 14 (for mild depression) was used to distinguish persons with depression from controls.

Blood sampling

Participants were invited to come to the study center for the baseline study visit after an overnight fast of at least 10 hours. Fasting blood was collected, and subsequently separated into plasma and serum, and aliquots were stored at -80°C for future analyses. Samples of 1934 persons with depression and 4620 controls were sent to Brainshake Ltd./Nightingale Health for analysis; samples were measured in April 2014.

Netherlands Study of Depression and Anxiety (NESDA)

Cohort description

The Netherlands Study of Depression and Anxiety (NESDA) is an observational longitudinal cohort study on the long term course and consequences of depressive and anxiety disorders.⁽¹²⁾ In total 2,981 participants aged 18 to 65 years were recruited between 2004 and 2007 through different settings: community, primary care and specialized mental health clinics in order to obtain a representative sample of persons with and without depressive and anxiety disorders.

Depression

During the baseline assessment, the presence of depressive disorders (MDD and dysthymia) and anxiety disorders (panic disorder, social phobia, generalized anxiety disorder and/or agoraphobia) was ascertained with the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSMIV)-based Composite Interview Diagnostic Instrument (CIDI, version 2.1, World Health Organization, 1997) by specially trained research staff. The CIDI has a high reliability and validity for the assessment of depressive and anxiety disorders.⁽¹³⁾ Persons with depression were defined as having a MDD in lifetime, whereas controls were defined as having no depressive or anxiety disorder in lifetime.

Blood sampling

After an overnight fast, EDTA plasma samples were collected and stored in aliquots at -80°C until further analysis. Blood samples were analyzed in 2 batches (April 2014 and December 2014) by Brainshake Ltd./Nightingale Health.

Statistical analysis

To account for potential batch difference, batch was added as an additional covariate in the analysis with NESDA data.

Netherlands Twin Registry (NTR)

Cohort description

The Netherlands Twin Registry (NTR) collects data from Dutch twins, other siblings, their parents and partners. Participants were recruited either at birth or when already older at start of NTR, through city councils in 1990-1991 and through additional efforts in later years. Participants are invited every 2 to 3 years to complete a survey that contains questions about health, lifestyle, personality and psychopathology. A detailed description of NTR can be found elsewhere.(14)

Depression

In a subsample of NTR participants, the lifetime version of the Composite Interview Diagnostic Instrument (CIDI) was administered to measure the presence of MDD. The CIDI has a high reliability and validity for the assessment of depressive disorders.(13) In a larger number of NTR participants, depression questionnaires were used. Cases with depression were defined as having a diagnosis of MDD in lifetime. Controls were defined as persons that scored below established cut-offs on depressive symptom questionnaires in every wave.

Blood sampling

Samples were drawn by venipuncture from the medial cubital vein during a home-visit, after centrifugation back at the laboratory at 4°C, plasma was aliquoted and stored at -20°C. Samples were collected in two biobanking initiatives (the first between June 2004 and July 2008 and the second between January 2011 and December 2011) prior to shipment to Brainshake Ltd./Nightingale Health for analysis. Samples were measured in April 2014 at Brainshake Ltd./Nightingale Health.

Statistical analysis

To account for family relatedness in the data, logistic generalized estimating equations were used in this cohort.

Rotterdam Study (RS)

Cohort description

The Rotterdam study (RS) is a large prospective population based cohort study, among people 55 years of age or older living in the well-defined Ommoord district in Rotterdam (The Netherlands) in 1990. Later the RS was expanded in 2000 and 2006 to include people 45 years of age or older living in the Ommoord district.(15)

Depression

Symptoms of depression were assessed with the CES-D.(3) The CES-D is a 20-item self-report scale designed to measure depressive symptomatology in the general population. A score of ≥ 16 is used to identify individuals at risk for clinical depression, with good sensitivity and specificity and high internal consistency.(4) Cases with depression were defined as having a CES-D score ≥ 16 during one of the measurement waves. Controls were defined as having a CES-D score < 16 in all of the measurement waves.

Blood sampling

Samples were collected after overnight fasting. Samples were drawn by venipuncture from the median cubital vein, after centrifugation back on site; plasma was aliquoted and stored at -80°C . Samples were not freeze-thawed prior to shipment to Brainshake Ltd./Nightingale Health for analysis. Samples were measured in April 2014 at Brainshake Ltd./Nightingale Health.

LifeLines-DEEP Study (LLD)

Cohort description

LLD is a sub-cohort of the LifeLines population cohort (167,729 subjects), which aims to assess the biomedical, socio-demographic, behavioral, physical and psychological factors that contribute to health and disease in a general Dutch population.⁽¹⁶⁾ A subset of approximately 1,500 LifeLines participants make up LLD. These subjects gave additional biological materials, including blood samples for metabolite profiling.⁽¹⁷⁾⁽¹⁸⁾ For the current study we focused on the 1024 LLD individuals for whom plasma metabolism and information on depression and confounders were available.

Depression

Depression mood was accessed by the MINI questionnaire, that was answered by all participants within 2 months prior to plasma sample collection.

Blood sampling

Samples were collected after overnight fasting. Samples were drawn by venipuncture from the median cubital vein, after centrifugation back on site; plasma was aliquoted and stored at -80°C. Samples were not freeze-thawed prior to shipment to Brainshake Ltd./Nightingale Health for analysis. Samples were measured in April 2014 at Brainshake Ltd./Nightingale Health.

Classification of depressed cases and controls

Controls were those with a negative diagnostic interview for lifetime depression, or had a score on the depression questionnaires below established cut-off scores (i.e. CES-D<16, HADS-D<8 and/or IDS-SR30<14). If multiple self-reports of depressive symptoms before blood sampling were available, controls needed to score below the established cut-offs during all these assessments. When diagnostic data on other psychiatric disorders were available (e.g. anxiety disorders), persons with other psychiatric disorders were excluded from the controls.

Metabolomics assessment

A total of 230 metabolites or metabolite ratios were reliably quantified from Ethylenediaminetetraacetic acid (EDTA) plasma samples using targeted high-throughput proton Nuclear Magnetic Resonance (¹H-NMR) metabolomics (Nightingale Health Ltd, Helsinki, Finland) (19). This platform provides simultaneous quantification of routine lipids, lipoprotein subclass profiling with lipid concentrations within 14 subclasses, fatty acid composition, and various low-molecular-weight metabolites including amino acids, ketone bodies and gluconeogenesis-related metabolites in molar concentration units. This metabolomics platform has been extensively used and described in numerous studies (see <https://nightingalehealth.com/publications> for an overview), including large-scaled epidemiological studies in the field of type 2 diabetes (20), cardiovascular disease (21), mortality (22), and lifestyle factors such as alcohol intake (23). Details of the experimentation and applications of the ¹H-NMR metabolomics platform have been extensively described previously (19, 24)(25).

The entire process from sample handling to data processing is highly standardized and fully automated. Samples were prepared irrespective of depression status, because depression cases and controls entered each study at random order (i.e. unrelated to depression status), and the laboratory analyzing the samples was unaware of depression cases vs. control status when preparing the samples. Automated liquid handlers mixed 260 μ L buffer (75 mM Na₂HPO₄ in 80%/20% H₂O/D₂O, pH 7.4; 4.64

mM sodium 3-(trimethylsilyl)propionate-2,2,3,3-d₄, and 6.15 mM sodium azide) with the plasma in 1:1 ratio and moved the prepared samples to 96-format racks of NMR tubes, which were subsequently moved to the robotic sample changer, cooled to refrigerator temperature. Each rack contained 2 quality control samples: 1 serum mimic and a mixture of 2 low-molecular-weight metabolites. For the native plasma samples, the lipoprotein (80k data points after 4 dummy scans using 8 transients, 90° pulse) and low-molecular-weight metabolites (64k data points, using 24 (or 16) transients acquired after 4 steady state scans, T2-relaxation-filtered pulse sequence) data were automatically collected at 310.1K either with the 500 MHz or the 600 MHz Bruker AVANCE IIIHD NMR spectrometer, with a relaxation delay of 3.0 seconds.(19)(25)

The NMR spectra are converted to absolute concentrations via Bayesian modeling performed via advanced proprietary software and integrates quality control checks. Several of the metabolic biomarkers have already been ‘validated’ with other techniques (i.e. routine clinical chemistry assays, gas chromatography, an enzymatic method, and/or mass spectrometry).(21, 24, 26–28) Furthermore, genetic studies(29–31) performed on the same metabolomics platform showed that the labels applied to the metabolites are coherent and linked with biologically relevant and plausible genes.

The 14 lipoprotein subclass sizes were defined as follows: extremely large VLDL with particle diameters from 75 nm upwards and a possible contribution of chylomicrons, five VLDL subclasses, IDL, three LDL subclasses and four HDL subclasses. The following components of the lipoprotein subclasses were quantified: phospholipids (PL), TG, cholesterol (C), free cholesterol (FC), and cholesteryl esters (CE). The mean size for VLDL, LDL and HDL particles was calculated by weighting the corresponding subclass diameters with their particle concentrations.

NMR spectroscopy provides highly consistent biomarker quantification. This is due to the inherently reproducible nature of the technology; the samples never come into contact with the radiofrequency detector in the NMR spectrometer. Biomarker quantification directly from plasma, without any sample extraction procedures, further contributes to the high reproducibility (24). Representative coefficients of variations (CVs) for the metabolic biomarkers are published as

Supplementary Data 3 in Kettunen *et al.*(30) with the CVs determined for 9,600 samples. Values ranged between 0.3 and 19.5 (mean 4.5%), and most values are comparable to routinely used assays in clinical chemistry.

Covariates

To be largely in line with previous metabolomics meta-analytic studies,(23); we adjusted analyses for the following potentially confounding variables: age (in years), gender, fasting status (yes/no), use of lipid modifying medication (yes/no), and current smoking (yes/no). The lipid modifying drugs were defined according to the related Anatomical Therapeutic Chemical Classification System (ATC) code C10 (Lipid modifying agents) in order to capture all the medications falling under this category, including the use of single agents (C10A - Lipid modifying agents, plain: C10AA HMG CoA reductase inhibitors; C10AB Fibrates; C10AC Bile acid sequestrants; C10AD Nicotinic acid and derivatives; C10AX Other lipid modifying agents) and all their potential combinations (C10B - Lipid modifying agents, combination: C10BA HMG CoA reductase inhibitors in combination with other lipid modifying agents; C10BX HMG CoA reductase inhibitors, other combinations). The antidepressant medications selected for the sensitivity analyses included all classes listed under the ATC code N06A (N06AA Non-selective monoamine reuptake inhibitors, N06AB Selective serotonin reuptake inhibitors, N06AF Monoamine oxidase inhibitors, non-selective, N06AG Monoamine oxidase A inhibitors, N06AX Other antidepressants). Given the bidirectional relationship between depression and obesity and their shared biological processes (including genes, endocrine and immuno-inflammatory mechanisms),(32) the role of obesity was explored in greater detail in sensitivity analysis (see Statistical analyses). Body mass index (BMI) was calculated as measured weight (kg)/length (m)², and divided into normal weight (BMI=18.50-24.99), overweight (BMI=25.00-29.99) and obesity (BMI≥30).

Assessment of potential bias due to metabolites data transformation

According to the standardized protocol of data processing applied in the present study a constant of 1 was added to the metabolite values before log-transformation. This common practice, adopted also in several other studies also from the same BBMRI-NL Metabolomics Consortium,(33) aims to achieve normalization of the distribution also for metabolites with initial values equaling zero. Nevertheless, it is important to acknowledge that this transformation may have had introduced some bias due to the high variability in the normal range of different metabolite. In the present analyses we aimed to estimate the potential degree of bias introduced by comparing the results of the metabolites-depression associations obtained applying three different transformation before log-transformation: A) adding a constant of 1; B) adding the value of the 10th percentile of the distribution (excluding 0 values) of each metabolite, a value therefore within the normal range of the original metabolite; C) excluding all 0 values, a more conservative approach.

Analyses were performed in the NESDA sample (N=2,509), the most representative dataset for the trait under study, which involves subjects well phenotyped in psychiatric terms including healthy controls and depressed patients from various settings and developmental stages of psychopathology. Furthermore, analyses focused on the 51 metabolites classified in the cluster of “lipids, fatty acids and various low-molecular-weight metabolites”.

Ridge plots in Figure S13 shows the distribution (per SD increase) of the (log)values of the metabolites after the three different transformation. The three sets of values were used in logistic regression analyses estimating the association between metabolites and lifetime depression, adjusting for gender, age, smoking, lipid modifying drugs and fasting status. Results were highly similar across the three transformations. In Figure S14, the estimates obtained used the original transformation A were plotted against estimates obtained with transformation B (panel 1), and against those obtained with transformation C (panel 2). In both instances the correlation between association effect sizes equaled 1 as the estimates were substantially identical across transformation (coefficient from regressing estimates of transformation A on those from transformation B = 1.02, se=0.01; coefficient from regressing estimates

of transformation A on those from transformation C = 1.00, se=0.02). Overall, these results suggest that the degree of bias potentially introduced by the transformation applied in original analyses is minimal and negligible.

Table S1. Overview of depression instruments and definitions per study

| | Depression | | Current depression* | | Controls | |
|------------|---|-------|---|-------|---|-------|
| | definition | n | definition | n | definition | n |
| CODAM DM | CES-D ≥ 16 at time of blood sampling | 34 | CES-D ≥ 16 at time of blood sampling | 34 | CES-D < 16 at time of blood sampling | 105 |
| CODAM noDM | CES-D ≥ 16 at time of blood sampling | 78 | CES-D ≥ 16 at time of blood sampling | 78 | CES-D < 16 at time of blood sampling | 338 |

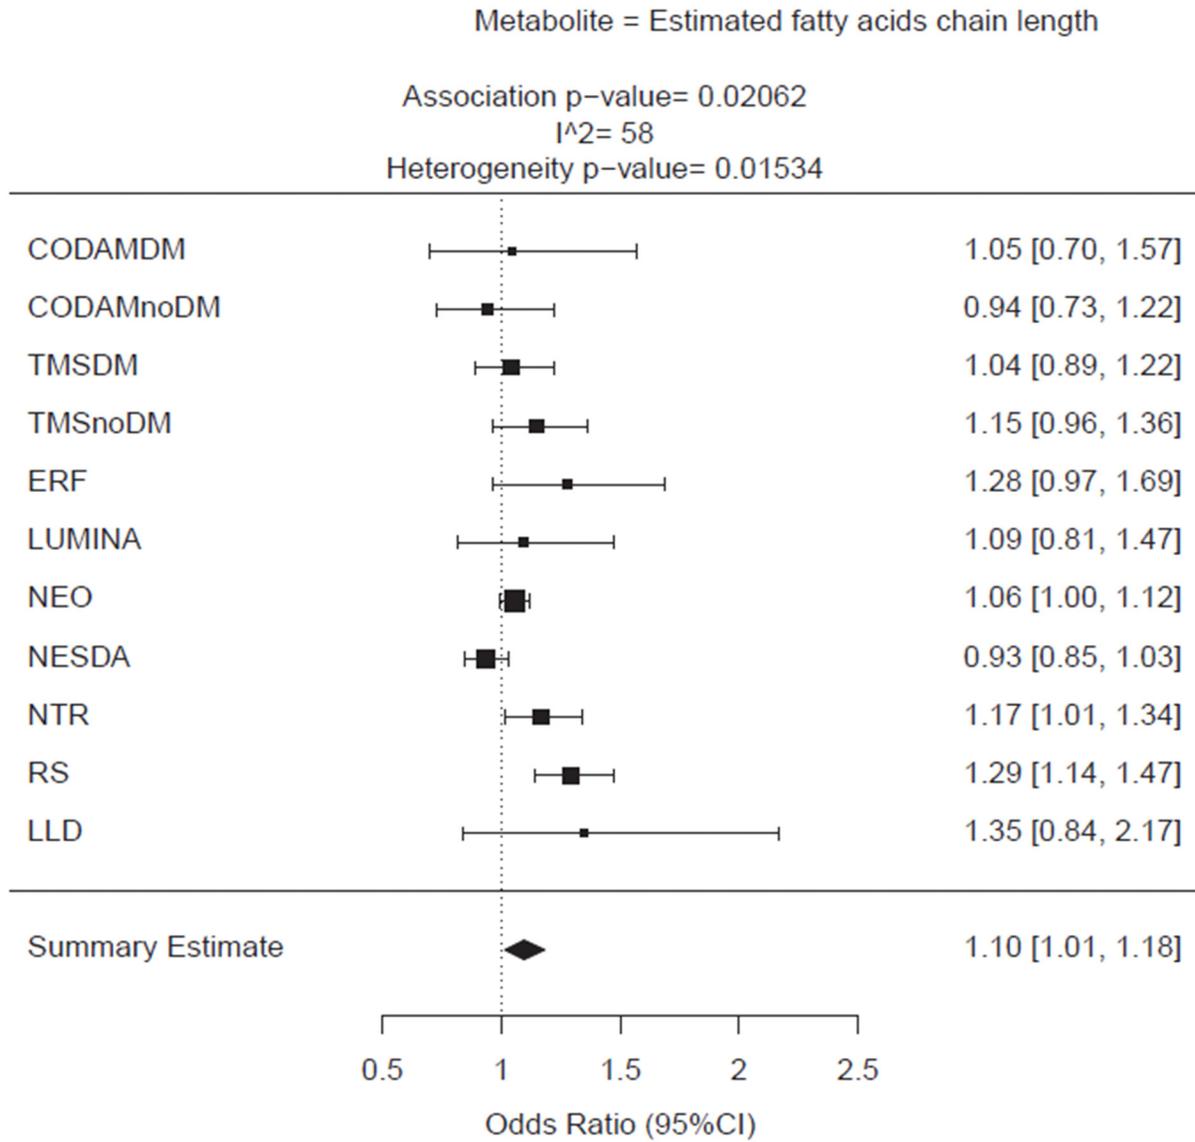

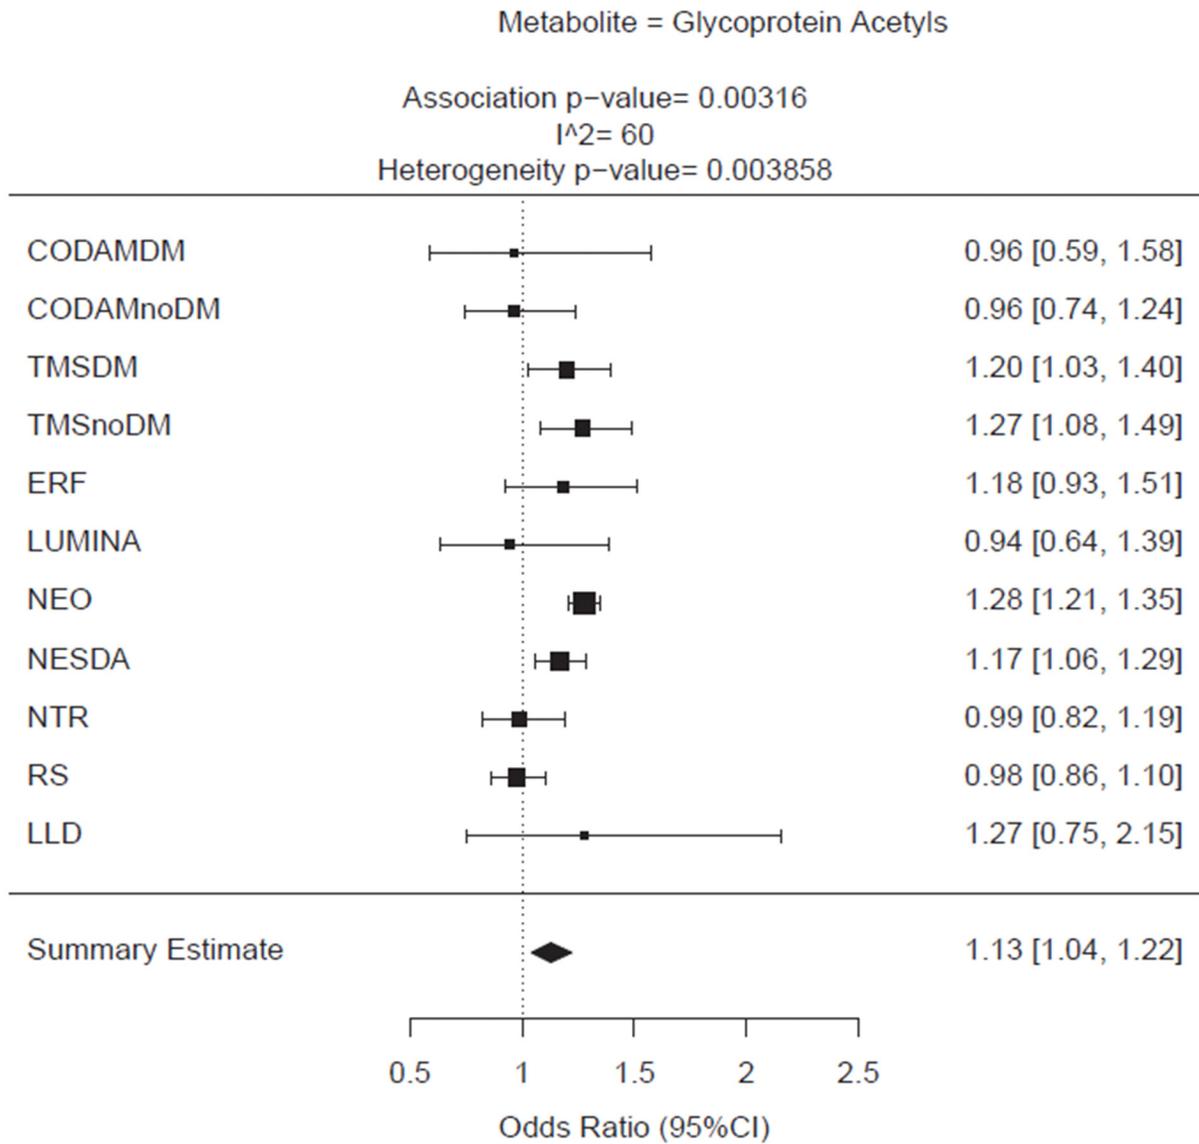

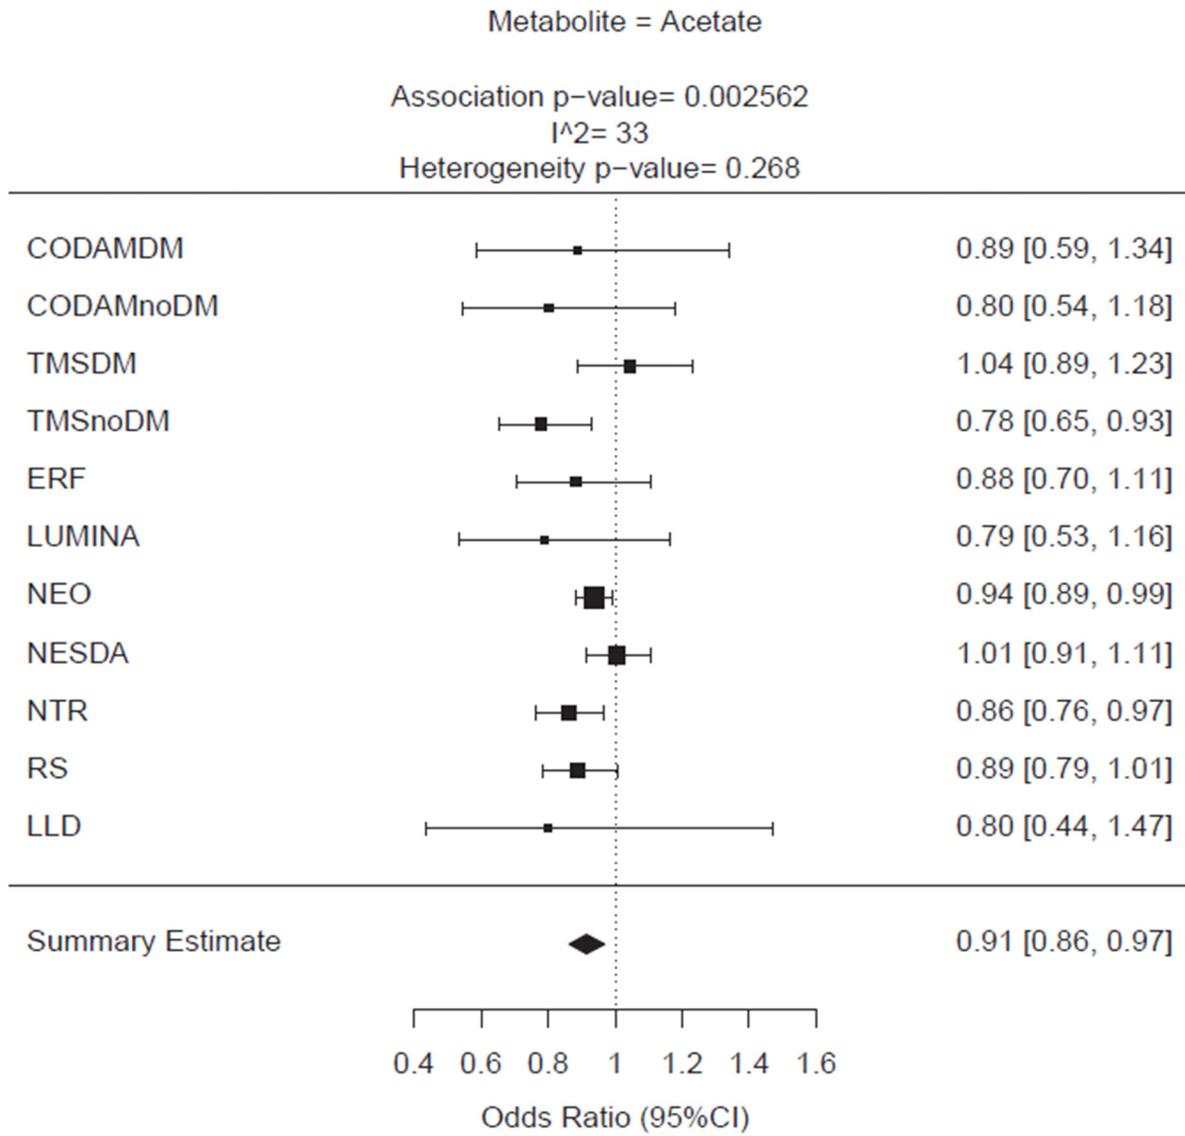

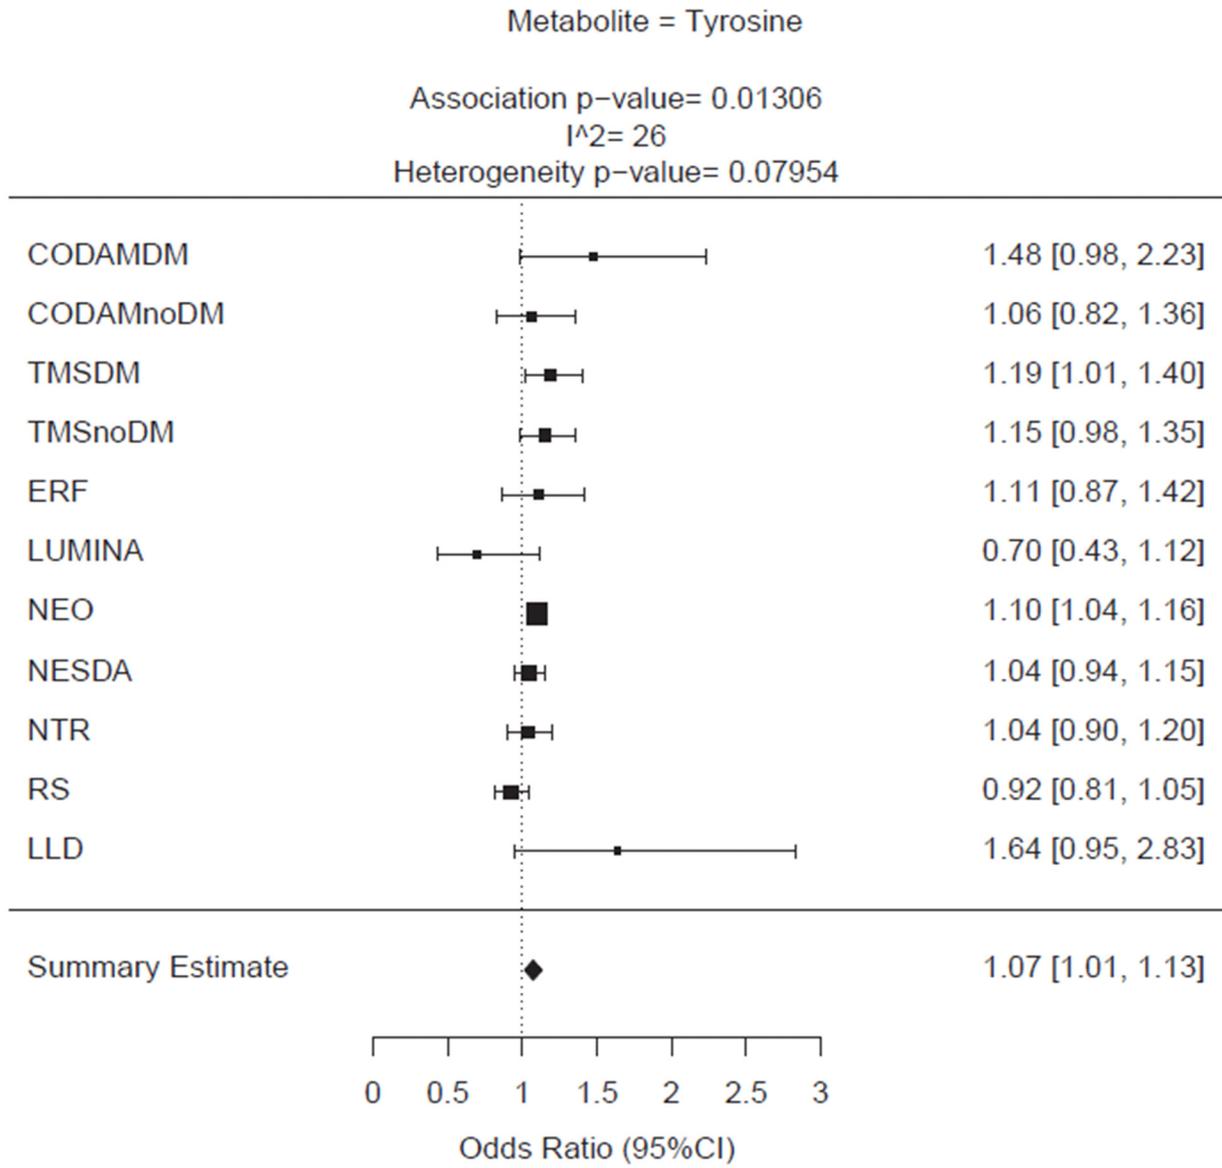

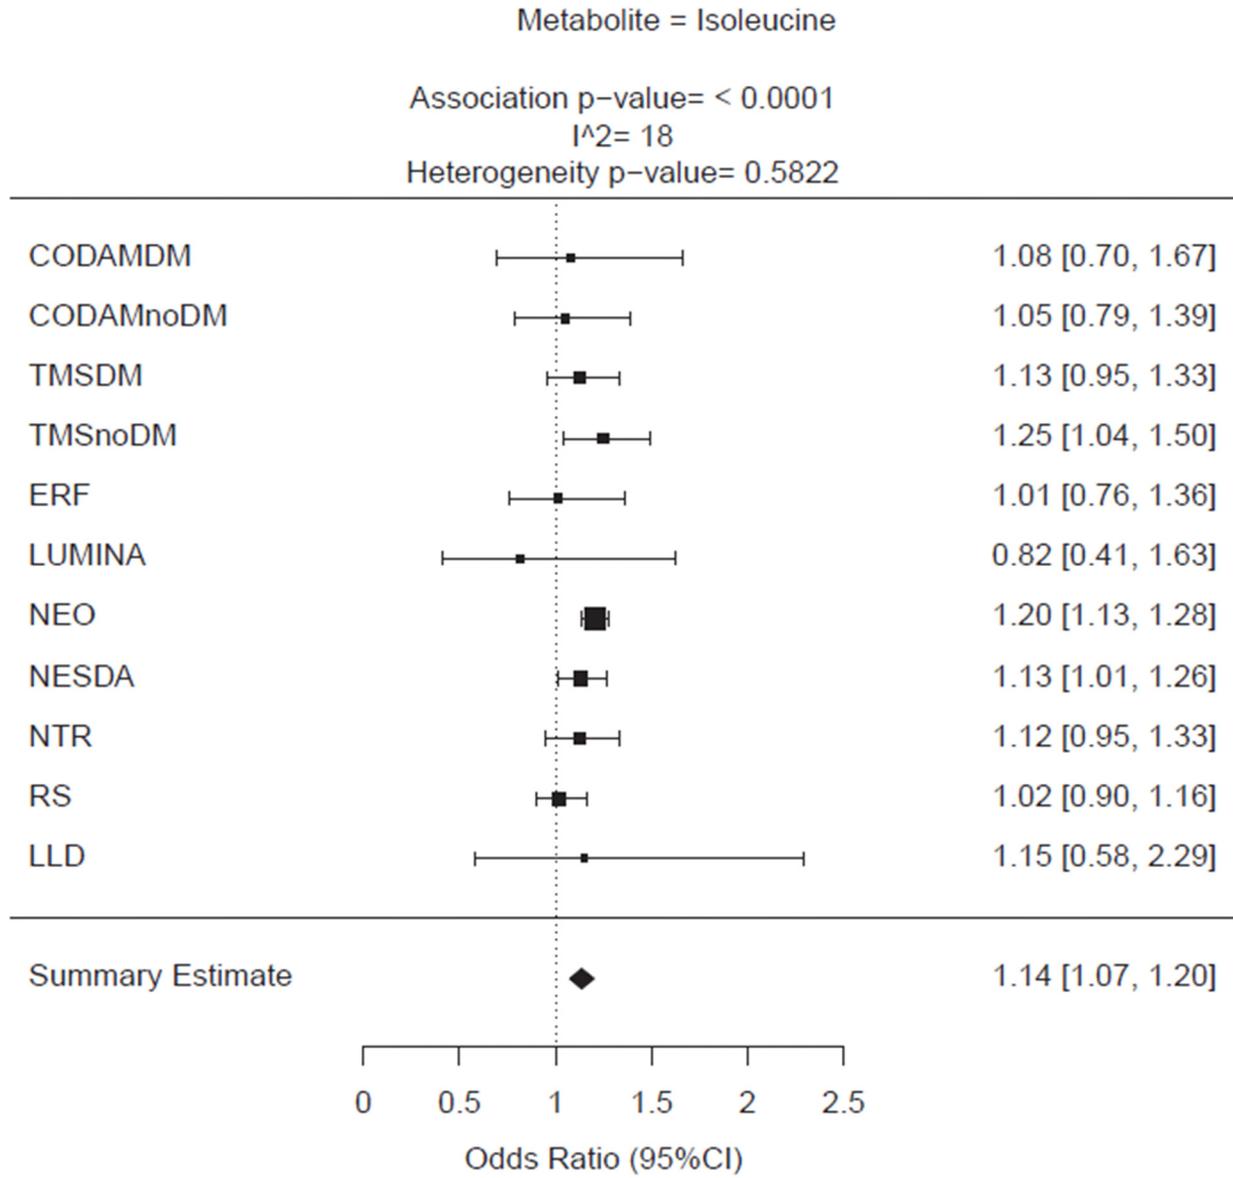

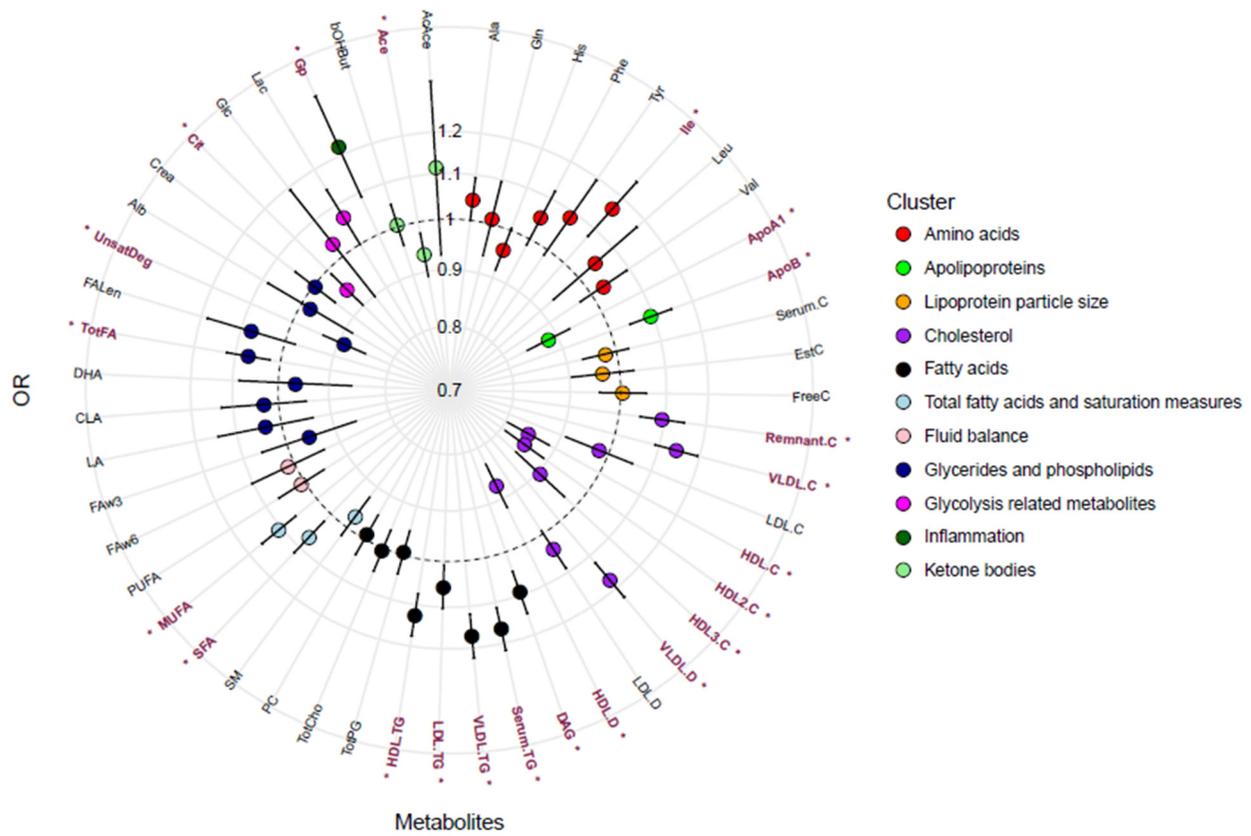

Figure S3. Pooled odds ratio and 95% confidence intervals for the association of the 51 lipids, fatty acids and various low-molecular-weight metabolites with current depression^a

^a Nineteen of the 22 significant metabolites were previously identified with the broader defined depression. In addition to these 19 metabolites, saturated fatty acid level was related to increased odds of current depression, whereas degree of unsaturation and citrate level were associated to a decreased odds of current depression. Tyrosine, by contrast, was associated with overall depression, but not with the more restricted current depression.
